

A quantitative approach to painting styles

Vilson Vieira*, Renato Fabbri, David Sbrissa, Luciano da Fontoura Costa, Gonzalo Travieso

Instituto de Física de São Carlos, Universidade de São Paulo (IFSC/USP), Brazil

HIGHLIGHTS

- Applied statistical mechanics methods to the analysis of painting styles.
- Philosophical concepts like dialectics were modeled as quantitative metrics.
- Wider dispersion of characteristics for Modern Art while superposition for Baroque.
- Confirms art history: Moderns are independent in style while Baroques share techniques.
- Painting shows increasing innovation. High opposition in Baroque–Modern transition.

ABSTRACT

This research extends a method previously applied to music and philosophy (Vilson Vieira et al., 2012), representing the evolution of art as a time-series where relations like *dialectics* are measured quantitatively. For that, a corpus of paintings of 12 well-known artists from baroque and modern art is analyzed. A set of 99 features is extracted and the features which most contributed to the classification of painters are selected. The projection space obtained provides the basis to the analysis of measurements. These quantitative measures underlie revealing observations about the evolution of painting styles, specially when compared with other humanity fields already analyzed: while music evolved along a master–apprentice tradition (high dialectics) and philosophy by opposition, painting presents another pattern: constant increasing skewness, low opposition between members of the same movement and opposition peaks in the transition between movements. Differences between baroque and modern movements are also observed in the projected “painting space”: while baroque paintings are presented as an overlapped cluster, the modern paintings present minor overlapping and are disposed more widely in the projection than the baroque counterparts. This finding suggests that baroque painters shared aesthetics while modern painters tend to “break rules” and develop their own style.

1. Introduction

Painting classification is a common field of interest for applications such as painter identification – e.g. assessing the authenticity of a given art work – style classification, paintings database search and more recently, automatic aesthetic judgment in computational creativity applications. Determining the best features for painting style characterization is a complex task on its own. Many studies [1–4] applied image processing to feature extraction for painter and art movements

identification. Manovich [5–7] uses features like entropy, brightness and saturation to map paintings and general images into a 2-dimensional space and, in this way, to visualize the difference between painters. There are also many related works dealing on feature selection for painting classification. Penousal et al. [8] use features based on aesthetic criteria estimated by image complexity while Zujovic et al. [9] evaluate a large set of features that most contribute to classification.

This study also analyzes a set of features which most contribute to the classification of paintings. Although, in contrast with previous works, it goes forward: the historic evolution of painting styles is analyzed by means of geometric measures in the feature space. Those measures are based on key concepts from Philosophy: *opposition*, *skewness* and *dialectics*. The dialectics, for instance, is defined by Hegel [10] as a method of argument where a synthesis solves the tension between two opposing ideas: thesis and antithesis. Those concepts are originally qualitative. In this study, thesis, antithesis and synthesis are defined as states in a time-series. The dialectics is then calculated as a quantitative measure: it is defined as the inverse distance between the synthesis state and the perpendicular bisector between thesis and antithesis states. The lower the distance, the greater the dialectics, because the synthesis state is near the perpendicular bisector that models the *ideal synthesis*. This quantitative approach is not meant to surpass the qualitative approach but to contribute in the understanding of human history.

To create the feature space, a set of 99 features is extracted from 240 images of 12 well-known painters. The first six painters of this group represent the baroque movement while the remaining six represent the modern art period. A feature selection process yields the pair of features which most contributed for the classification. Similar results using LDA (Linear Discriminant Analysis) are obtained, which reinforce the feature selection method.

After feature selection, a centroid for each group of paintings is calculated which defines a *prototype*: a representative work-piece for the respective cluster. The set of all prototypes following a chronological order defines a time-series where the main purpose of this study is performed: the quantitative analysis of the historical evolution of art movements. Extending a method already applied to music and philosophy, [11] *opposition*, *skewness* and *dialectics* measurements are taken. These concepts are central in philosophy – e.g. philosophers from antiquity like Aristotle and Plato developed their ideas using the dialectics method while it is also found in modern works like Hegelian and Marxist dialectics – and humanistic fields, however lack studies from a quantitative perspective [10]. Represented as geometric measures, these concepts reveal interesting results and patterns. Modern paintings groups show minor superposition when compared with baroque counterparts suggesting the independence in style found historically in modernists and strong influence of shared painting techniques found in baroque painters. Dialectics and opposition values presented a peak in the transition between baroque and modern periods – as expected considering history of art – with decreasing values in the beginning of each period. Skewness index is presented with oscillating but increasing values during all the time-series, suggesting a constant innovation through art movements. These results present an interesting counterpart with previous results in philosophy – where opposition is strong in almost entire time-series – and in music—where the dialectics is remarkable [11].

The study starts describing the corpus of paintings used and a review of both aesthetic and historic facts regarding baroque and modern movements (Section 2). The image processing steps used to extract features from these paintings are presented followed by the feature selection. The results are then discussed in Section 3 with basis on geometric measurements in the projected feature space—considering the most clustered projection and LDA components.

2. Modeling painting movements

2.1. Painting corpus

A group of 12 well-known painters is selected to represent artistic styles or movements from baroque to modernism. Six painters are chosen to represent each of these movements. The group is presented in Table 1 together with their more representative style, in chronological order. It is known that painters like Picasso covered more than one style during his life. For example, only the Cubist style is considered for Picasso, even though the artist developed other styles during his career.

For each painter, 20 raw images are considered from the database of public images organized by Wikipedia. Examples of selected paintings titles and their respective creation years are listed in Table 2 and all the paintings are listed in Table B.1 in Appendix B.¹

It is interesting to review some historical and aesthetic characteristics from baroque and modern movements before entering into the quantitative analysis in Section 3 where those hypotheses are further discussed. Baroque is marked by tradition, a desire to portray the truth (found in Caravaggio, Frans Hals and Velázquez), the beauty (Poussin, Vermeer), the nature and the sacred (Caravaggio, Rembrandt). A remarkable use of light contrast (as in the “*chiaroscuro*” technique mastered by Caravaggio), disregarding simple equilibrium in composition and preference for complex oppositions, both compound aesthetic characteristics which baroque artists used to represent their ideas. The transmission of those techniques from one painter to another is common in baroque. Modernists, on the other hand, did not follow “rules”. Each modern painter employed or created new ways to represent ideas. As noted by Gombrich: “[they] craved for an art that does not consist of tricks that could be learned, for a style that is not a mere style, but something strong and powerful like the human

¹ The source code together with all the 240 raw images are available online at <http://github.com/automata/ana-pintores>.

Table 1
Painters ordered chronologically with the artistic style they represent.

Artists	Remarkable styles/movements
Caravaggio	Baroque, Renaissance
Frans Hals	Baroque, Dutch Golden Age
Nicolas Poussin	Baroque, Classicism
Diego Velázquez	Baroque
Rembrandt	Baroque, Dutch Golden Age, Realism
Johannes Vermeer	Baroque, Dutch Golden Age
Vincent van Gogh	Post-Impressionism
Wassily Kandinsky	Expressionism, Abstract art
Henri Matisse	Modernism, Impressionism
Pablo Picasso	Cubism
Joan Miró	Surrealism, Dada
Jackson Pollock	Abstract expressionism

passion” [12]. van Gogh pursued this artistic trend in his intense use of colors and the caricature aspect of his paintings. Paul Gauguin searched for “primitive” in his paintings. Others, like Seurat, applied physical properties of the chromatic vision and started painting the nature like a collection of color points, and ended creating the pointillism. Modernists created a new style for each of their experiments using their own techniques to represent a nature outside the domains already covered by their predecessors.

2.2. Image processing

All 240 images are resized to 800×800 pixels and cropped to consider a region positioned in the same coordinates and with same aspect for all original paintings. Although details are lost from the original image, windowing is necessary as the paintings have varying sizes and aspect ratios (for instance, Pollock has paintings with larger width than height when compared with Caravaggio or van Gogh) and some of the image measurements are size dependent. After windowing, the images are pre-processed by applying histogram equalization and median filtering with a 3-size window. Feature extraction algorithms are applied to colored, gray-scale or binary versions of images as necessary (e.g. convex-hull used a binary image, whereas Haralick texture used the gray-scale image and SLIC segmentation analysis was applied to color images). Curvature measurements are extracted from segments of paintings identified by the SLIC segmentation method [13] as presented in Fig. 2. The whole process is represented schematically in Fig. 1 and covers all the steps from image processing through measurements, discussed in the following sections.

2.3. Extracted features

To create a *painting space* a number of distinct features extracted by computational methods from raw images of the paintings are considered. The features are related with aesthetic characteristics and aim to quantify properties well-known by art critics. All the features are summarized in Table 3 and detailed, grouped in classes, in the following list.

Shape features: after image segmentation, a number of shape descriptors are calculated for each segment, represented as a binary matrix. *Perimeter* is measured as pixel-length of the segment contour. *Area* is estimated by counting the number of pixels representing the segment. A convex-hull of the segment is used to calculate the *convex area* and its ratio to the original segment area. The *number of constituent segments* for each painting is also considered as a descriptor. *Circularity* reveals how much a shape remembers a circle and is obtained by the ratio between perimeter and area of the segment.

Texture and complexity features: to estimate image complexity, a number of *entropy* measures of its energy (squared FFT coefficients) are computed—listed in the first quarter of Table 3. Together with entropy, a more specific family of measurements is considered for texture characterization: the 14 *Haralick texture features* [14] are calculated for this purpose.

Curvature: this descriptor has an interesting biological motivation related to the human visual system—e.g. object recognition is related to the identification of corners and high curvature points [15]. These points have more information about object shape than straight lines or smooth curves. In this sense, curvature is well suited for the characterization of the considered paintings. Curvature $k(t)$ of a parametric curve $c(t) = (x(t), y(t))$ is defined as:

$$k(t) = \frac{\dot{x}(t)\ddot{y}(t) - \dot{y}(t)\ddot{x}(t)}{(\dot{x}(t)^2 + \dot{y}(t)^2)^{\frac{3}{2}}} \quad (1)$$

t being the arc-length parameter and $\dot{x}(t)$, $\dot{y}(t)$, $\ddot{x}(t)$ and $\ddot{y}(t)$ are respectively the first and second order derivatives of $x(t)$ and $y(t)$. These derivatives are obtained through Fourier transform and convolution theorem:

$$\dot{x} = \mathfrak{F}^{-1}(2\pi i\omega X(\omega)) \quad (2)$$

$$\dot{y} = \mathfrak{F}^{-1}(2\pi i\omega Y(\omega)) \quad (3)$$

Table 2

Some of the 240 selected paintings and their respective authors and year of creation. All the paintings are listed in [Appendix B](#) in [Table B.1](#).

Painter	Painting title	Year
Caravaggio	Musicians	1595
	Judith Beheading Holofernes	1598
	David with the Head of Goliath	1610
Frans Hals	Portrait of an unknown woman	1618/20
	Portrait of Paulus van Beresteyn	1620s
	Portrait of Stephanus Geeraerds	1648/50
Nicolas Poussin	Venus and Adonis	1624
	Cephalus and Aurora	1627
	Acis and Galatea	1629
Diego Velázquez	Three musicians	1617/18
	The Lunch	1618
	La mulatto	1620
Rembrandt	The Spectacles-pedlar (Sight)	1624/25
	The Three Singers (Hearing)	1624/25
	Balaam and the Ass	1626
Johannes Vermeer	The Milkmaid	1658
	The Astronomer	1668
	Girl with a Pearl Earring	1665
Vincent van Gogh	Starry Night Over the Rhone	1888
	The Starry Night	1889
	Self-Portrait with Straw Hat	1887/88
Wassily Kandinsky	On White II	1923
	Composition X	1939
	Points	1920
Henri Matisse	Self-Portrait in a Striped T-shirt	1906
	Portrait of Madame Matisse	1905
	The Dance (first version)	1909
Pablo Picasso	Les Demoiselles d'Avignon	1907
	Guernica	1937
	Dora Maar au Chat	1941
Joan Miró	The Farm	1921/22
	The Tilled Field	1923/24
	Bleu II	1961
Jackson Pollock	No. 5	1948
	Autumn Rhythm	1950
	Blue Poles	1952

$$\ddot{x} = \mathfrak{F}^{-1}(-(2\pi\omega)^2 X(\omega)) \quad (4)$$

$$\ddot{y} = \mathfrak{F}^{-1}(-(2\pi\omega)^2 Y(\omega)) \quad (5)$$

where \mathfrak{F}^{-1} is the inverse Fourier transform, X and Y are the Fourier transform of x and y respectively, ω is the angular frequency and i is the imaginary unit (see [Fig. 2](#)).

The calculation of the derivatives ($\dot{x}(t)$, $\dot{y}(t)$) and ($\ddot{x}(t)$, $\ddot{y}(t)$) by a numerical method (i.e. Fourier transform) is sensitive to high frequency noise [15]. A low-pass filter can be used to compensate this effect. A Gaussian filter is then applied to the signal and defined as

$$g(t) = \frac{1}{2\pi\sigma^2} \exp\left(-\frac{t^2}{2\sigma^2}\right) \quad (6)$$

and its Fourier transform is given by

$$G(\omega) = \exp\left(\frac{-(2\pi)^2\omega^2}{(2/\sigma)^2}\right). \quad (7)$$

Using the convolution theorem it is possible to apply the Gaussian filter $g(t)$ to the signal:

$$\hat{\dot{x}}(t) = \dot{x} * g(t) = \mathfrak{F}^{-1}(\dot{X}(\omega)G(\omega)) \quad (8)$$

$$\hat{\dot{y}}(t) = \dot{y} * g(t) = \mathfrak{F}^{-1}(\dot{Y}(\omega)G(\omega)) \quad (9)$$

$$\hat{\ddot{x}}(t) = \ddot{x} * g(t) = \mathfrak{F}^{-1}(\ddot{X}(\omega)G(\omega)) \quad (10)$$

Fig. 1. A summary of all steps from image processing through feature extraction through time-series and measurements calculation (skewness, opposition and dialectics).

$$\hat{y}(t) = \dot{y} * g(t) = \mathfrak{S}^{-1}(\ddot{Y}(\omega)G(\omega)) \quad (11)$$

where $*$ represents the convolution operation, obtaining the first and second order multi-scale derivatives $(\hat{x}(t), \hat{y}(t))$ and $(\hat{\ddot{x}}(t), \hat{\ddot{y}}(t))$ for both $x(t)$ and $y(t)$. These are the derivatives used to calculate curvature $k(t)$ (Eq. (1)) free from high frequency noise.

The corresponding features are calculated from the curvature $k(t)$: the *mean* and *standard deviation* of data, the *number of peaks* and the *distance* (geometric and in pixels) between peaks. It is important to note that a *peak* is defined as a high curvature point. A point a is considered a peak if its curvature $k(a)$ satisfies the following criteria:

$$k(a) > k(a - 1) \quad (12)$$

$$k(a) > k(a + 1) \quad (13)$$

$$k(a) > \tau \quad (14)$$

τ being the corresponding threshold defined as

$$\text{median}(k) \gamma \quad (15)$$

where γ is a factor obtained empirically as values which reveal the desired level of curvature details.

2.4. Measurements

N_f features define an N_f -dimensional space, also called *painting space* where the following measurements are calculated [11]. For simplification, a prototype \vec{p}_i is defined for each class C_i of all the N_i feature vectors \vec{f}_j . Each prototype summarizes a painting class, being its *centroid*, calculated in the projected space as:

$$\vec{p}_i = \frac{1}{N_i} \sum_{j=1}^{N_i} \vec{f}_j. \quad (16)$$

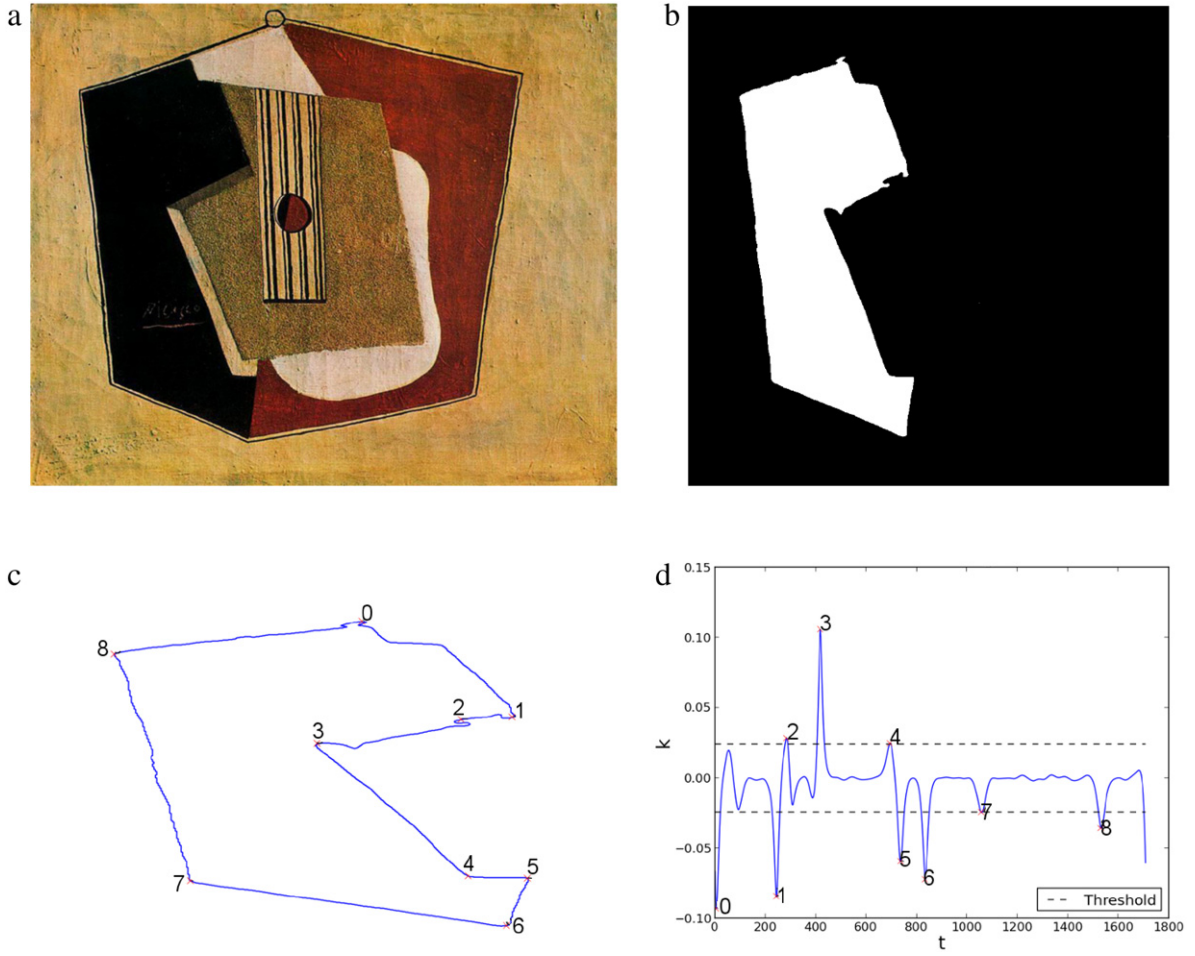

Fig. 2. (a) The original paintings image. (b) A segmented region. (c) The extracted curvature of segment. (d) The parametric curve $k(t)$ with peaks given by a particular threshold.

A sequence S of \vec{p}_i states ordered chronologically defines a time-series. The average state at time i of states \vec{p}_1 through \vec{p}_i is defined as:

$$\vec{a}_i = \frac{1}{i} \sum_{j=1}^i \vec{p}_j. \quad (17)$$

The opposite state defines an opposition measure from \vec{p}_i as

$$\vec{r}_i = \vec{p}_i + 2(\vec{a}_i - \vec{p}_i) \quad (18)$$

and in this way an opposition vector can be defined:

$$\vec{D}_i = \vec{r}_i - \vec{p}_i. \quad (19)$$

Knowing that any displacement from one state \vec{p}_i to another state \vec{p}_j is defined as

$$\vec{M}_{i,j} = \vec{p}_j - \vec{p}_i \quad (20)$$

it is possible to define an *opposition index* to quantify how much a prototype \vec{p}_j opposes \vec{p}_i (a displacement in direction of \vec{r}_i) or emphasizes \vec{p}_i (a displacement in $-\vec{r}_i$ direction):

$$W_{i,j} = \frac{\langle \vec{M}_{i,j}, \vec{D}_i \rangle}{\|\vec{D}_i\|^2}. \quad (21)$$

However, the movements in such *painting space* are not restricted to confirmation or refutation of “ideas”. Alternative ideas can exist out of this dualistic displacement. When an idea shows an alternative movement – besides the opposition

movement – that explores a new region of the *painting space*, it is said the idea is an innovation. This is modeled as a *skewness index* which quantifies how much a prototype \vec{p}_j is innovative when compared with \vec{p}_i :

$$s_{i,j} = \sqrt{\frac{|\vec{p}_i - \vec{p}_j|^2 |\vec{a}_i - \vec{p}_i|^2 - [(\vec{p}_i - \vec{p}_j)(\vec{a}_i - \vec{p}_i)]^2}{|\vec{a}_i - \vec{p}_i|^2}}. \quad (22)$$

Another measure arises when considering three consecutive states at times i , j and k . \vec{p}_i being the thesis, \vec{p}_j the antithesis and \vec{p}_k the synthesis, a *counter-dialectics index* can be defined as being

$$d_{i \rightarrow k} = \frac{|\langle \vec{p}_j - \vec{p}_i, \vec{p}_k \rangle + \frac{1}{2} \langle \vec{p}_i - \vec{p}_j, \vec{p}_i + \vec{p}_j \rangle|}{|\vec{p}_j - \vec{p}_i|} \quad (23)$$

or, the distance between \vec{p}_k and the perpendicular bisector (or middle-hyperplane for N_f -dimensional spaces) between \vec{p}_i and \vec{p}_j . In other words, a \vec{p}_k state with higher $d_{i \rightarrow k}$ is far from the synthesis (low dialectics) and vice-versa.

2.5. Feature selection

To select the most relevant features a dispersion measure of the clusters is applied using scatter matrices [15]. For all the N_p paintings, considering all possible combinations of feature pairs $F_{N_p,a}$ and $F_{N_p,b}$, the S_b (between class) and S_w (within class) scatter matrices are calculated with $K = 12$ classes, one class C_i for each painter:

$$S_w = \sum_{i=1}^K S_i \quad (24)$$

$$S_b = \sum_{i=1}^K N_i (\vec{\mu}_i - \vec{M})(\vec{\mu}_i - \vec{M})^T \quad (25)$$

with N_i the number of paintings in class C_i and the scatter matrix for class C_i defined as

$$S_i = \sum_{\vec{f} \in C_i} (\vec{f}_i - \vec{\mu}_i)(\vec{f}_i - \vec{\mu}_i)^T \quad (26)$$

Table 4

Feature pairs $F_{N_p,a}$ and $F_{N_p,b}$ ordered by α . Pairs with higher α present better dispersion and clustering. The best feature pairs μ of curvature peaks and μ of number of segments are selected for analysis and metrics calculation.

Pair nr.	Feature a	Feature b	α
1	μ of curvature peaks	μ of number of seg.	42.445
2	μ of number of seg.	μ of convex-hull area	37.406
3	μ of segments perimeter	μ of number of seg.	36.703
4	μ of segments area	μ of number of seg.	36.214
5	μ of number of segments	μ convex/original	34.885
6	μ of circularity (Per. ² /Area)	μ of number of seg.	33.540
7	Energy μ of image rows (green)	μ of number of seg.	32.954
8	Energy μ of rows and columns (green)	μ of number of seg.	32.954
9	Energy σ of image rows (green)	μ of number of seg.	32.932
10	Energy σ of rows and columns (green)	μ of number of seg.	32.906
11	μ of local entropy (5-size window)	μ of number of seg.	32.898
12	Entropy (Haralick adj. 4)	μ of number of seg.	32.898
13	Entropy (Haralick adj. 3)	μ of number of seg.	32.883
14	Entropy (Haralick adj. 1)	μ of number of seg.	32.874
15	Entropy (Haralick adj. 2)	μ of number of seg.	32.869
16	Energy μ of image rows ($r.$)	μ of number of seg.	32.865

where \vec{f}_i is an object of the feature matrix F whose rows and columns correspond to the paintings and its features $F = [\leftarrow f_i^T \rightarrow]$ and $\vec{\mu}_i$ and \vec{M} are the mean feature vectors for the N_i objects in class C_i and for all the N_p paintings in the projection, respectively:

$$\vec{\mu}_i = \frac{1}{N_i} \sum_{i \in C_i} \vec{f}_i \quad (27)$$

$$\vec{M} = \frac{1}{N_p} \sum_{i=1}^{N_p} \vec{f}_i. \quad (28)$$

The trace of within- and between-class ratio can be used to quantify dispersion:

$$\alpha = \text{tr}(S_b S_w^{-1}). \quad (29)$$

Large values of α reveal larger dispersion and the features which relate with large values of α are selected for the analysis (Section 3.1).

3. Results and discussion

3.1. Best features

By calculating α using Eq. (29) for all possible feature pairs $F_{N_p,a}$ and $F_{N_p,b}$ of the $N_f = 99$ features and ordering the results by α , it is possible to select the features which are most relevant to classification: pairs with high α present better dispersion and clustering than pairs with lower values. As shown in Table 4 (and Fig. 3), features μ of curvature peaks and μ of number of segments have the higher α and are selected to opposition, skewness and dialectics analysis—both features are shown as predominant also in LDA, discussed in the next section. It is interesting to note the nature of selected features: the number of segments and curvature peaks is the most prominent characteristics for the classification of paintings, even better than texture or image complexity. Other features presenting large values of α – like μ of convex-hull area, segments perimeter and area, and circularity – are also related with shape characteristics. Both features presented a similar projection and clustering properties of Fig. 3 as shown in Fig. A.1.

The projected painting space considering all the $K = 12$ groups of paintings that are “represented” by their prototype (i.e. centroid) \vec{p}_i is presented in Fig. 3. The time-series S – a sequence of all the prototype states \vec{p}_i arranged in a chronological order (Section 2.4) – is also shown in the figure as vectors. The projection reveals well clustered groups with minor superposition, mainly for modern paintings.

A striking result is the high distance which Pollock stays when compared with the other painters: it is a consequence of the lag number of segments present in works of Pollock (the y-axis being the projection of this feature: μ of segments number). Therefore, both the x-axis (μ of curvature peaks) and y-axis are relevant to separate the baroque and modern art movements. It is possible to note a separation between baroque and modern painters where the baroque paintings are arranged in an overlapping group while the modern painters are more clustered and separated from each other while covering a widely region of the painting space. This is confirmed by the history of art with modern painters being more individualistic in their styles while baroque painters share aesthetic characteristics in their paintings. The same observation arises when following the time-series, the difference between the movements is clear: while baroque artists tend to present a recurring pattern,

Fig. 3. Projected *painting space* considering the best pair of features: μ of curvature peaks and μ of number of segments.

an abrupt displacement separates van Gogh – the first modern painter in the *painting space* – from the previous, and breaks the cyclic pattern. van Gogh, although located near the baroque painters and in the opposite extreme of modern painters, represents a transition to the modern period and after him the following vector displacements will continue until the higher transition in Pollock.

Using an index for clustering evaluation – based on Davies–Bouldin [16] index – it is possible to check how clustered each group of paintings is around a given centroid \vec{p}_i . This measure is defined as a cluster scattering index T_i for each cluster C_i :

$$T_i = \sqrt{\frac{1}{N_i} \sum_{j=1}^{N_i} |\vec{f}_j - \vec{p}_i|^2} \quad (30)$$

which represents the mean distance from each painting \vec{f}_j to its centroid \vec{p}_i . This index was normalized by a global scattering index $T_{\vec{g}}$:

$$T_{\vec{g}} = \sqrt{\frac{1}{N_p} \sum_{i=1}^{N_p} |\vec{f}_i - \vec{g}|^2} \quad (31)$$

where \vec{g} is the global centroid: the mean vector considering all N_p paintings. The ratio $T_i/T_{\vec{g}}$ (Table 5) gives a measurement of how scattered each cluster is relative to the global dispersion of paintings. In other words, it is possible to check the uniformity of painting style for a single author: painters with higher $T_i/T_{\vec{g}}$ values present less uniformity of style, while lower values reveal more homogeneous works by a given painter. In general, baroque painters present more homogeneous works than modern painters. Modern painters seem to explore more the *painting space* than baroque painters.

While analyzing the baroque group separately, it is possible to observe a trajectory drawn by Caravaggio and Frans Hals through Poussin which ends with the opposite (and back forth) movement of Velázquez. It can be attributed to the influence of the “*chiaroscuro*” master on these painters, mainly in Velázquez who is known to have studied the works of Caravaggio [12]. It arises again in the return to the Caravaggio movement by Vermeer—some critics affirm [17] that painters like Vermeer could not have even existed without Caravaggio’s influence: Vermeer and Caravaggio clusters are the most superimposed considering all the portraits in the *painting space*. Both facts are confirmed by the histograms of gray levels shown in Fig. 4. Velázquez and Vermeer histograms are more similar to Caravaggio’s histogram than the remaining baroque painters.

Table 5

Cluster scattering index T_i for each cluster C_i and the ratio between T_i and the global cluster scattering index T_g . The ratio measures how scattered the paintings in a given cluster are. Painters with lower T_i/T_g values present more homogeneous works than painters with higher values of T_i/T_g .

Artists	T_i	T_i/T_g
Caravaggio	0.026	0.110
Frans Hals	0.074	0.302
Poussin	0.028	0.117
Velázquez	0.016	0.066

Miró	0.053	0.217
Pollock	0.073	0.302

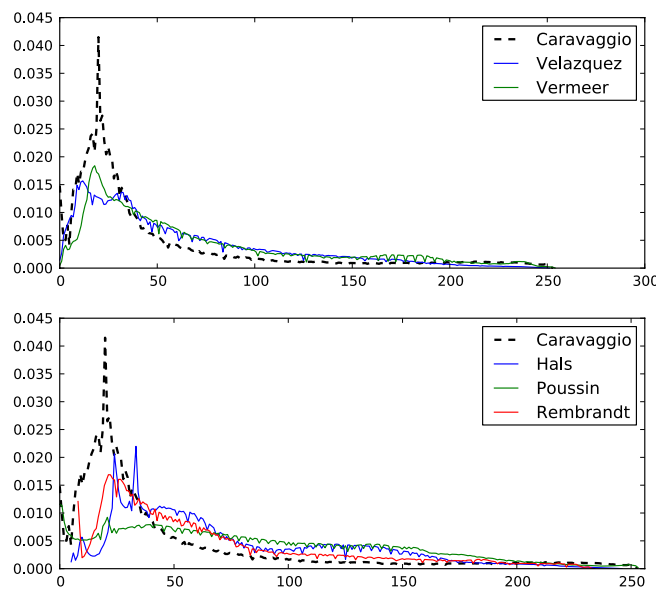

Fig. 4. Mean gray levels histograms for all the baroque painters. Vermeer and Velázquez show more similarity with Caravaggio than other baroque painters.

In summary, the baroque group shows a strong inter-relationship by comparing with modern painters where the absence of super-impositions is remarkable. Again, this suggests a strong style-centric distinction among artists of the modern era while baroque artists shared techniques and aesthetic characteristics. This is also confirmed when comparing the histograms of modern paintings in Fig. 5: smaller similarities are observed between the considered artists, contrasting with baroque painters shown in Fig. 4.

When considering opposition and skewness, more interesting results arise, as shown in Table 6 and Fig. 6. Clearly, the larger value for opposition is attributed to Rembrandt. This is surprising given that the Dutch master figures as a “counterpoint” of baroque even being part of this art movement [12]. Vermeer also presents strong opposition and the nature of his paintings (e.g. domestic interior, use of bright colors) could explain this phenomenon. A pattern is shown in the beginning of baroque and modern art: an opposition decrease is present in both cases, which is followed by an increase in opposition. Henceforth, a following plateau of high opposition values is observed in baroque painters. This plateau happens in the transition period between baroque and modern art, gradually decreasing while the modern artists begin to take their place in history. These decreasing opposition values reflect a low opposition role between first artists of baroque period and increasing opposition as long as the period is moving into modernism, although skewness values remain oscillating and increasing during almost all the time-series. This characterizes again a common scene in arts, mostly in modernists, each one trying to define his own style and preparing to change into a new movement. In summary, the *painting space* is marked by constantly increasing skewness, strong opposition in specific moments of its evolution (the transition between baroque and modern) and minor opposition between the artists of the same movement.

Fig. 5. Mean gray levels histogram for all the modern painters. There are minor similarities between modern artists.

Fig. 6. Opposition $W_{i,j}$ and skewness $s_{i,j}$ values for the two best features.

Table 6

Opposition and skewness indices for each of the twelve moves from a painter to the next.

Painting move	$W_{i,j}$	$s_{i,j}$
Caravaggio → Frans Hals	1.0	0.0
Frans Hals → Poussin	0.111	0.425
Poussin → Velázquez	0.621	0.004
Velázquez → Rembrandt	1.258	0.072
Rembrandt → Vermeer	1.152	0.341
Vermeer → van Gogh	1.158	0.280
van Gogh → Kandinsky	0.970	0.452
Kandinsky → Matisse	0.089	0.189
Matisse → Picasso	0.117	0.509
Picasso → Miró	0.385	0.325
Miró → Pollock	2.376	3.823

The counter-dialectics, shown in Table 7 and Fig. 7, draws a parallel with the opposition and skewness curves. It reinforces the already observed facts: painters of the same movement show initially decreasing followed by increasing counter-dialectics reflecting the concordance of members of the same movement and their preparation to change into the next movement. The larger counter-dialectics happens in van Gogh and Kandinsky: again, the point where baroque ends and modern art starts, regarding the painters selected for this study.

Fig. 7. Counter-dialectics values considering the two best features.

Table 7

Counter-dialectics index for each of the ten subsequent moves among painters states for the best two features.

Painting triple	$d_{i \rightarrow k}$
Caravaggio → Frans Hals → Poussin	0.572
Frans Hals → Poussin → Velázquez	0.337
Poussin → Velázquez → Rembrandt	0.151
Velázquez → Rembrandt → Vermeer	0.608
Rembrandt → Vermeer → van Gogh	1.362
Vermeer → van Gogh → Kandinsky	1.502
van Gogh → Kandinsky → Matisse	1.062
Kandinsky → Matisse → Picasso	0.183
Matisse → Picasso → Miró	0.447
Picasso → Miró → Pollock	2.616

Table 8

Opposition and skewness indices for each of the twelve painters states moves.

Painting move	$W_{i,j}$	$s_{i,j}$
Caravaggio → Frans Hals	1.0	0.0
Frans Hals → Poussin	−0.101	0.132
Poussin → Velázquez	0.588	0.037
Velázquez → Rembrandt	1.526	0.050
Rembrandt → Vermeer	1.101	0.143
Vermeer → van Gogh	1.153	0.157
van Gogh → Kandinsky	1.279	0.512
Kandinsky → Matisse	0.179	0.149
Matisse → Picasso	−0.201	0.516
Picasso → Miró	0.432	0.163
Miró → Pollock	4.031	2.662

3.2. All the features

Although features $F_{Np,a}$ (μ of curvature peaks) and $F_{Np,b}$ (μ of number of segments) are shown as an interesting choice for classification, LDA is applied considering all the $N_f = 99$ features to test the relevance of these features and the stability of the results. The LDA method [15] projected the features in a 2-dimensional space that better separates the paintings and yields a time-series as done for the two most prominent features. The first two components give the time-series shown in Fig. 8. It is possible to note, as expected, a similarity with results from Section 3.1. The skewness indices show even more an ascending curve along the entire evolution, as presented in Table 8 and Fig. 9. The opposition and dialectics (Table 9 and Fig. 10) patterns remain.

Fig. 8. Time series yielded by 2-dimensional projected “painting space” considering the two first components obtained by LDA transformed into the $N = 99$ feature matrix.

Fig. 9. Opposition and Skewness values considering the time series for all the features. The same patterns observed when analyzing the best feature pair remains in this observation.

For LDA validation, the total set of paintings is split into two groups: a training set with 10 random selected paintings for each artist and a test set with the remaining 10 paintings for each artist, without repetition. Such a validation is performed 100 times. The confusion matrix (Fig. 11) reveals the quality of the predicted output. Diagonal elements represent the mean number of samples for which the predicted class is equal to the true class, while off-diagonal elements indicate the ones that are unclassified by LDA. Higher diagonal values indicate more correct predictions. As observed, the LDA method performed

Table 9

Counter-dialectics index for each of the ten subsequent moves among painters states for the best two components of LDA projection.

Painting triple	$d_{i \rightarrow k}$
Caravaggio → Frans Hals → Poussin	0.587
Frans Hals → Poussin → Velázquez	0.317
Poussin → Velázquez → Rembrandt	0.268
Velázquez → Rembrandt → Vermeer	0.736
Rembrandt → Vermeer → van Gogh	1.192
Vermeer → van Gogh → Kandinsky	2.352
van Gogh → Kandinsky → Matisse	0.974
Kandinsky → Matisse → Picasso	0.241
Matisse → Picasso → Miró	0.704
Picasso → Miró → Pollock	1.924

Fig. 10. Counter-dialectics values (higher values reveal lower dialectics) considering all the features. The pattern observed in the best pair projection became stronger here: it is possible to observe clearly the highest value along the movement transition period (van Gogh and Kandinsky).

as expected for the considered set of paintings. The best classified samples are Pollock paintings which is expected given the high detachment of this cluster observed in the presented projections. In general, the confusion matrix reflects facts previously discussed: a similarity between baroque painters, mainly Velázquez, Caravaggio and Rembrandt and a separation between painters before and after van Gogh which defines the frontier between the baroque and modern movements.

4. Conclusions

It is shown that two features: (a) the number of curvature peaks and (b) the number of segments of an image – both related with shape characteristics – can be used for the classification of the selected painters with remarkable results, even when compared with canonical feature measures like Haralick or image complexity. Such relevance is supported by the analysis of a dispersion index calculated for every pair of features and reinforced by LDA analysis.

The effective characterization of selected paintings by means of these features allowed the definition of a “painting space”. While represented as states in this projected space, the baroque paintings are shown as an overlapped cluster. The modern paintings clusters, in contrast, present minor overlapping and are disposed more widely in the projection. These observations are compatible with the history of art: baroque painters shared aesthetics while modern painters tend to define their own styles individually [12].

A time-series – composed by prototype states representing each painter chronologically – allowed the concepts of opposition, skewness and dialectics to be approached quantitatively, as geometric measures. The painting states show a decrease in opposition and dialectics considering the first members of the same movement (baroque or modern) followed by increasing opposition and dialectics until it reaches the strong opposition momentum between the two movements. Also, the skewness curve increases during almost entire time-series. This could reflect a strong influence role of a movement in its members together with an increasing desire to innovate, present in each artist, stronger in modernists.

Fig. 11. Confusion matrix for LDA. Half of the paintings are used as a training set and the other half as a test set. The validation is performed 100 times. Diagonal elements show the mean number of paintings in the predicted class (a painter) which equals the true class.

Both opposition, skewness and dialectics measurements can be compared with results already obtained for music and philosophy [11]. Music composers seem to be guided by strong dialectics due to the recognized master–apprentice role. Philosophers movements, otherwise, are strong in opposition. Painters, as this study reveals, show increasing skewness, and strong values for both opposition and counter-dialectics in specific moments of history—i.e. baroque–modern transition.

While not sufficient to exhaust all the characteristics regarding an artist or its work, this method suggests a framework to the study of arts by means of a feature space and geometrical measures. As a future work, the number of painters could be increased and a set of painters could be specifically chosen to analyze influence (e.g. works of Frans Hals' sons can be included to verify the influence of their father and master, or paintings by Rafael, Poussin and Guido Reni [12] or Carracci can be compared to confront the already known similarity of both painters). A larger number of paintings for each artist could be considered for analysis as well. Although this study promotes a quantitative approach, qualitative features can be used, as done in a previous work for musicians and philosophers [11]. A comparison between results obtained for quantitative and qualitative features can then be applied. The same framework can be applied to other fields of interest like Movies or Poetry. Another interesting use of this framework – being currently developed by the authors – is a component of a generative art model: geometrical measures in the *painting space* (like the already defined dialectics or opposition and skewness) can guide an evolutionary algorithm, assigning the value of measures as the fitness of generated material. This model complements a framework to the study of creative evolution in arts.
